Abstract Cancer epidemiology has undergone marked development since the nineteen-fifties. One of the most spectacular and specific contributions was the demonstration of the massive effect of smoking and genetic polymorphisms on the occurrence of bladder cancer. The tobacco carcinogens are metabolized by various xenobiotic metabolizing enzymes, such as the super-families of Nacetyltransferases (NAT) and glutathione S-transferases (GST). DNA repair is essential to an individual's ability to respond to damage caused by tobacco carcinogens. Alterations in DNA repair genes may affect cancer risk by influencing individual susceptibility to this environmental exposure. Polymorphisms in NAT2, GST and DNA repair genes alter the ability of these enzymes to metabolize carcinogens or to repair alterations caused by this process. We have conducted a case-control study to assess the role of smoking, slow NAT2 variants, GSTM1 and GSTT1 null, and

XPC, XPD, XPG nucleotide excision-repair (NER) genotypes in bladder cancer development in North Tunisia. Taken alone, each gene unless NAT2 did not appear to be a factor affecting bladder cancer susceptibility. For the NAT2 slow acetylator genotypes, the NAT2*5/*7 diplotype was found to have a 7-fold increased risk to develop bladder cancer (OR=7.14; 95% CI: 1.30–51.41). However, in tobacco consumers, we have shown that Null GSTM1, Wild GSTT1, Slow NAT2, XPC (CC) and XPG (CC) are genetic risk factors for the disease. When combined together in susceptible individuals compared to protected individuals these risk factors give an elevated OR (OR=61). So, we have shown a strong cumulative effect of tobacco and different combinations of studied genetic risk factors which lead to a great susceptibility to bladder cancer.

Introduction

The chain of events from environmental exposures to cancer requires hundreds of polymorphic genes encoding proteins involved in the transport and metabolism of xenobitics, or in DNA repair, or in immune or inflammatory response [1]. Once introduced into organism, these xenobiotics are bio-transformed by several enzymes.

The xenobiotic-metabolizing machinery includes oxidative enzymes (phase I), which generally activate compounds that become carcinogenic and phase II conjugating enzymes, considered mainly protective since they detoxify a number of reactive chemical carcinogens [2]. The conjugating process (phase II) is controlled by the super families of glutathione S-transferases and N-acetyltransferases enzymes.

Genetic polymorphisms affecting these enzymes can modify their activity with an effect on individual susceptibility for cancers which are induced by DNA damage [3].

The absence of GSTM1 activity is due to a homozygous deletion in the GSTM1 gene (GSTM1*0 or GSTM1 null genotype). Subjects lacking GSTM1 are at increased risk of cancer, particularly lung and bladder cancer that are environmentally-related cancers [4, 5].

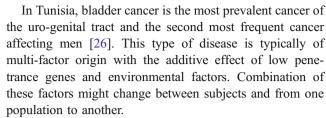

Lack of GSTT1 enzyme activity has been reported in several studies as associated with increased risk for bladder and lung cancers [6, 7]. However, some studies reported that the risk of cancer was increased only among those with the GSTT1 positive (wild-type) genotype [8, 9].

The N-acetyltransferase (NAT) enzymes catalyze the N-acetylation of aromatic amine, which is considered a detoxifying process, expressed in multiple tissues, such as the bladder urothelium [10, 11]. A number of single nucleotide polymorphisms (SNPs) have been reported in the NAT2 coding region. NAT2*4 is considered the "wild-type" allele or haplotype. The genetic alterations underlying the NAT2 polymorphism have been correlated with decreased NAT2 enzyme activity [12].

Indeed, the presence of one or 2 wild-type alleles results in a rapid or an intermediate acetylator phenotype, whereas carrying two mutant alleles results in a slow acetylator phenotype. NAT2 alleles containing the 191G>A (NAT2*14), 341T>C (NAT2*5), 590G>A (NAT2*6), or 857G>A (NAT2*7) SNPs are the slow acetylator NAT2 variants. The slow acetylator phenotypes were found to have an increased risk of bladder cancer among cigarette smokers [13, 14]. Indeed, smokers who are NAT2 slow acetylators have higher levels of 4-aminobiphenyl (ABP) hemoglobin adducts [15, 16]. Furthermore, ABP-DNA adducts in high grade bladder tumors are found at higher levels in smokers who are slow NAT2 acetylators [17, 18].

The alterations caused by carcinogens exposure are generally removed by DNA repair enzymes to assure DNA integrity. The nucleotide-excision repair (NER) pathway has been reported to be the most significant modulator of bladder cancer risk, with other pathways playing less prominent roles [19]. Polymorphisms in NER genes may cause variations in DNA repair capacity and increase susceptibility to bladder cancer through complex gene—gene and gene—smoking interactions [20].

Xeroderma pigmentosum complementation group C, D and G polymorphisms (XPC Lys939Gln, XPD Lys751Gln and XPG Asp1104His, respectively) has been hypothesized to have a role in bladder cancer risk, but results from prior molecular epidemiologic studies and genotype-phenotype analyses are conflicting [21–25]. The most important result in Caucasian population that has been reported in association with increased risk of bladder cancer was the mutated homozygous Lys939Gln for XPC [22].

Bladder cancer is a pertinent model to study such genetic and environmental factors interaction. In order to concretely illustrate this concept, we performed a case-control study with the aim of investigating the combined effect on bladder cancer of selected variations in two different pathway genes GSTM1, GSTT1, NAT2, XPC, XPD and XPG according to tobacco smoking in the Northern Tunisian population.

Material and Methods

Subjects

A total of 125 patients with bladder urothelial cell carcinoma (UCC) and 125 healthy controls were included in the present study. Patients were recruited from the Department of Urology at the Charles Nicole Hospital in Tunis. All were from North of Tunisia, 90% of them were men and their mean age at diagnosis was 67.14±9.5. The control group consisted of non-related healthy subjects without history of malignant disease who were matched to those in the case group for gender proportion, geographic origin, and age. Smoking status information was available for all controls and only for 109 patients. Under informed consent, peripheral blood samples were collected into tubes with EDTA (pH 8).

DNA Preparation and Genotyping

Genomic DNA was extracted from leukocytes using a phenole/chloroform procedure [27]. The quality of genomic DNA was controlled by electrophoresis on a 1% agarose gel stained with ethidium bromide. GSTM1 and GSTT1 null alleles were identified using a multiplex-polymerase chain reaction (PCR)-based method as described by Arand et al. [28]. For NAT2, a PCR was carried out as described by Hsieh et al. [29]. The whole intronless NAT2 gene resulted in 1093-base pair amplification. It was then digested with 5 U of KpnI (Promega), 10 U of BamHI (Promega), 5U of TaqI (Promega) and 10U of AluI (Promega), to reveal NAT2*5, NAT2*7, NAT2*6, and NAT2*14 alleles, respectively. Digestion was performed overnight at 37°C for KpnI, BamHI, and AluI and at 65°C for TaqI. The obtained fragments were separated in 2% agarose gel. Individuals with 2 wild alleles (NAT2*4/*4) were classified as rapid

acetylators, whereas the others were classified as intermediate acetylators when they had one mutant allele, and as slow acetylators when they had 2 mutant alleles including NAT2*5, NAT2*6, NAT2*7, or NAT2*14 [30, 31].

Polymorphisms for XPC Lys939Gln, XPD Lys751Gln and XPG Asp1104His are detected by PCR followed by digestion with PvuII, PstI and Hsp92II enzymes (Promega), respectively. Digestion was performed during 4 h at 37°C for all enzymes and the obtained fragments are separated in 2.5% agarose gel. Primers used in this study have been previously described [32, 33].

Statistical Analysis

Relative risks were estimated by calculating the odds ratios (OR) with 95% confidence intervals (CI) at the 0.05 (χ 2 test with Yates' correction, and Fisher's exact test) significance level [34]. Departures from Hardy-Weinberg equilibrium were tested using the software package Arlequin (version 3.01).

Results

Among the bladder cancer patients, 16% (20/125) were non-smokers and 71.2% (89/125) used 20 packs a year or more. Among the control group, 53.6% (67/125) were non-smokers versus 46.4% (58/125) smokers (Table 1). The comparison of patients and control group according to tobacco status shows that smoking is a risk factor for bladder cancer development (p=9.5 10^{-6} ; OR=3.99; CI 95% 2.08–7.69).

Genotype distributions for GSTM1, GSTT1, NAT2, XPC, XPD and XPG in 125 bladder cancer cases and 125 controls are summarized in Table 1. The distribution of GSTT1, GSTM1 null genotypes (GSTM1*0 and GSTT1*0), SNPs of the NAT2 gene and XPC, XPD and XPG variations among both groups were in agreement with the Hardy-Weinberg equilibrium.

Frequencies of the GSTM1 null genotype in the control group and bladder cancer cases were 44.8% and 50.4%, respectively (Table 1). The comparison of GSTM1*0 frequencies in the groups of patients and controls did not show a significant statistic difference (p=0.44). Study of the combined effect of smoking and GSTM1 genotypes in bladder cancer cases and controls suggests that smokers with the GSTM1 null genotype were at 6.40-fold increased risk for developing bladder cancer when compared to nonsmokers carrying the wild-type GSTM1 genotype (Table 2). Frequencies of the GSTT1 null genotype in the control group and bladder cancer cases were 30.4% and 24%, respectively (Table 1). As the GSTM1*0 variant, the GSTT1*0 polymorphism did not appear to be a factor for bladder cancer susceptibility (p=0.31). Studied separately, XPC, XPD and XPG mutated genotypes did not appear to affect bladder cancer susceptibility when compared to wild genotypes as a reference group (p value=0.56, 0.21 and 0.91, respectively).

The frequencies of NAT2*4, NAT2*5, NAT2*6, NAT2*7, and NAT2*14 variants in the control group as compared with bladder cancer cases were 51.6% versus 43.2%; 43.6% versus 48.4%; 2% versus 1.2%; 2.8% versus 5.2%; and 0% versus 2%, respectively (data not shown). NAT2 genotypes were categorized as homozygous mutant (slow), heterozygous wild-type/mutant (intermediate), and homozygous wild-type (rapid). The NAT2 genotype frequencies of the case group (22.4% rapid, 41.6% intermediate and 36% slow) were not significantly different from the control group (32% rapid, 39.2% intermediate and 28.8% slow), with p values estimated at 0.24 and 0.11 (Table 1). In contrast, a significant difference in genotypic frequencies between cases and controls was detected for the NAT2*5/*7 diplotype (p=0.01). This genotype was found to be overrepresented in patients and presented a 7-fold increased risk of developing bladder cancer as compared to the control group (OR=7.14; 95% CI: 1.30-51.41).

When patients genotypes were considered according to tobacco status (Table 2), null GSTM1, wild GSTT1, slow NAT2, XPC (CC), XPD (AA + AC) and XPG (CC) were respectively revealed as risk genotypes in smoker patients. Indeed, the risk value given by smoker status considered alone is OR=4.

While, smokers harboring separately slow NAT2 or mutated homozygous genotype for XPC were at 11 to 12-fold increased risk for developing bladder cancer when compared to non-smokers with respectively rapid NAT2 or wild type XPC (Table 2).

To investigate and evaluate the additive effects of these genetic risk factors, we have shown in Table 3 the association, according to the smoker status, of multiple factors simultaneously and with different possible combinations on bladder cancer susceptibility.

Non-smokers, harboring respectively GSTM1 wild, GSTT1 null, rapid and intermediate NAT2, XPC (AA + AC), XPD (CC) and XPG (GG + GC) were supposed to be protected.

Since our studied cancer is a multifactorial pathology which depends on additive effects of multiple risk factors, a single factor by itself should be without any effect on bladder cancer susceptibility. Hence, we supposed that protected individuals are non-smokers carrying zero to one (0–1) genetic risk factor. Considered as references, frequencies of these protected individuals are compared with those of persons at risk for bladder cancer which are smokers carrying at least one, two, three, four or five genetic risk factors.

Our results presented in Table 3 show that the population number decreases with the increase of risk factors analyzed simultaneously. We have also found a progressive increase

in OR, according to the number of analyzed genetic risk factors. These values of OR were increased from 7.46 to a maximal value of 61 ($p=3\ 10^{-5}$; OR=61.75; CI 95% 5.25–1711.89) when 4 risk factors were studied simultaneously in smoker patients.

Discussion

We have undertaken this case-control study to investigate the combined effect of smoking, slow NAT2, GSTM1 and GSTT1 null genotypes, XPC, XPD and XPG on susceptibility to bladder cancer in a Tunisian population. In the control group, our results confirmed the frequency of the GSTM1 null genotype (GSTM1*0) previously reported for healthy Tunisians and for the Caucasian population [35, 36]. However, the GSTT1*0 frequency was lower than that

reported for healthy Tunisians and was higher than that observed in the Caucasian population [35, 36]. Frequencies of the GSTM1 and GSTT1 null genotypes in the control group were compared to those found in bladder cancer cases. Our results indicated that the GSTM1 null genotype was not associated with bladder cancer susceptibility. When we stratified patients and controls according to their smoking status, our data suggested an additive effect of tobacco and GSTM1 null genotype but the smoking effect was predominant. This result was in agreement with a meta-analyses performed by Garcia-Closas et al. [21], which showed that the GSTM1 null genotype increases the overall risk of bladder cancer in smokers.

For the GSTT1 gene, our results suggested that the GSTT1 null genotype was not associated with bladder cancer risk. Of the published studies, some suggested an increased risk with the GSTT1 null genotype [13, 37] and

others reported no association [38]. In our study, the comparison of patients and controls according to the GSTT1 genotype and tobacco status suggested an aggravating effect of wild-type GSTT1 genotype in smokers, which confirmed the study of Kim et al. [39].

For the NAT2 gene, we have shown that the frequencies of alleles encoding slow acetylator variants NAT2*5, NAT2*6, NAT2*7, and NAT2*14 were similar to that reported for the Caucasians populations [40]. Globally, the NAT2 slow acetylator in our control group, collected in the North of Tunisia, was 28.8%. This value is lower than that reported in other studies on the middle coast of Tunisia (49.7%) [41] and also lower than that observed among American Caucasians [42]. The comparison of the slow NAT2 frequency in controls to that reported for patients without stratification did not show a significant statistic difference (p=0.19). A significant difference in genotypic frequencies between cases and controls was only detected for the NAT2*5/*7 diplotype (p=0.01). This genotype was found to be over-represented in patients and presented a 7-fold increased risk of developing bladder cancer compared to the control group. This association could be explained by the presence of the NAT2*5 haplotype. Indeed, some studies found that bladder cancer risk was high in individuals possessing NAT2*5 haplotypes [13, 43]. The 341T>C (I114T) SNP associated with NAT2*5 alleles or haplotypes yields a very large reduction in NAT2 activity [44] resulting from protein degradation [45]. However, we have reported that the homozygous genotype of NAT2 (NAT2*5/NAT2*5) was not associated with an increased risk of bladder cancer, which suggested that the NAT2*5 haplotype would act preferentially in association with the NAT2*7 haplotype. N-acetylation is considered as a major detoxification step for carcinogenic aromatic arylamines. The comparison of patients and controls according to the NAT2 genotype and tobacco status has shown a significant statistical difference which was in agreement with several other results [13, 14, 46]. These studies reported that in smokers, slow NAT2 increases the quantity of electrophilic-active products which induces local somatic mutations in oncogenes and/or anti-oncogenes, initiating tumoral progression.

For XPC, XPD and XPG mutated alleles; frequencies were reported for the first time in Tunisia and estimated at 33%, 29%, and 38%, respectively (results are submitted). These frequencies were higher than those reported in Caucasian and American population [22, 24]. The comparison of patients and controls according to XPC, XPD and XPG genotypes without any stratification did not show any significant statistical differences. However, according to tobacco status, important significant difference in genotypic frequencies between cases and controls was detected for

smokers carrying mutated homozygous genotype for XPC compared to the reference group (p=0.0001, OR=11.63; CI 95%: 2.80–52.30).

Xeroderma pigmentosum type C (XPC) encodes an important DNA damage recognition protein that binds to damaged DNA at a very early stage during DNA repair [47]. Our result confirmed other studies previously reported on XPC polymorphism association with bladder cancer [22, 48]

Bladder cancer is a multifactorial pathology; it seems that several genetic risk factors are involved in the development of the disease. Hence, one single factor alone should be without influence and should not affect bladder cancer susceptibility. In our case-control study, we have compared genotypic frequencies of the different studied genes between protected individuals (nonsmokers carrying zero to one genetic risk factor) and individuals at risk (smokers with at least one, two, three, four or five genetic risk factors). We have concluded that more a subject presents risk factor more the susceptibility to the disease increases as shown by OR increasing value. The simultaneous association of 5 risk factors along with cigarette smoker status gives a very high probability to develop bladder cancer. This result can be explained by the fact that persons who are exposed to high intensity of tobacco carcinogens are unable to detoxify these components especially if they carry altered xenobiotic enzymes, and are unable to eliminate mutations caused by DNA adducts if they present in addition an altered DNA repair enzymatic pathway.

According to our results, smoker status, NAT2 slow and intermediate genotypes, the GSTT1 wild-type allele, GSTM1 null genotype, XPC and XPG mutated genotypes are additive factors leading to bladder cancer. Mainly most of our patients present at least one of the studied risk factors, but the risk for bladder cancer increases with the number of accumulated risk factors.

Smoker status is the main environmental risk factor, however, in our study some patients with bladder cancer were non smokers or low smokers, among whom, four non-smoker persons were without or with only one genetic risk factor (Table 3) indicating that some other factors, that we have not investigated yet, could be involved in the bladder cancer.

Indeed, according to previous results, we have shown that polymorphism in genes encoding enzymes implicated in folate metabolism are also risk factor for bladder cancer [49].

In conclusion, to our knowledge, this is the first study achieved in Tunisia and particularly in North Tunisia presenting evidence that the risk of bladder cancer was very high for smokers having the association of 4 genetic risk factors involving different enzymatic pathways.
